QCD tests in τ decays with optimized perturbation expansion

P. A. Rączka[a*]

The next-to-next-to-leading order perturbative QCD corrections to R_τ and the higher moments of the invariant mass distribution in the hadronic tau decays are considered. The renormalization scheme dependence of these corrections is discussed. The optimized predictions are obtained, using the principle of minimal sensitivity as a guide to select the preferred renormalization scheme. A simplified fit is performed, using R_τ and R_τ^{12}, to see how the use of the optimized expansion may affect the determination of the α_s and the dimension six condensates from the experimental data.

Recently there has been considerable interest in the QCD predictions for the total hadronic width of the τ and the higher order moments of the invariant mass distribution in the hadronic τ decays [1–4]. These quantities have been used to obtain tight experimental constraints on α_s and the condensates. In spite of the high precision which may be obtained in fits to the experimental data it is important to investigate in detail how the results may be affected by the renormalization scheme (RS) dependence of the perturbative QCD predictions. Usually the $\overline{MS}$ scheme [5] is used to evaluate the perturbative QCD corrections. However, there is a two-parameter freedom in the choice of the RS in the next-to-next-to-leading order (NNLO), and there is no *a priori* theoretical or phenomenological reason why the $\overline{MS}$ scheme should be preferred. The difference in predictions obtained in various schemes is formally of higher order in the coupling, but numerically it may be significant, particularly at the energy scale of $m_\tau = 1.777$ GeV.

The QCD prediction for the R_τ ratio

$$R_\tau = \frac{\Gamma(\tau \to \nu_\tau + hadrons)}{\Gamma(\tau \to \nu_\tau e^- \overline{\nu}_e)}, \qquad (1)$$

has the form [6]

$$R_\tau = 3 S_{CKM} S_{EW} (1 + \delta_{pt}^{tot} + \delta_m^{tot} + \delta_{SVZ}^{tot}), \qquad (2)$$

where $S_{CKM} = (|V_{ud}|^2 + |V_{us}|^2) \approx 1$. The factor $S_{EW} = 1.0194$ represents the corrections from electroweak interactions. The δ_{pt}^{tot} contribution denotes the purely perturbative QCD correction, evaluated for three massless quarks. The δ_m^{tot} contribution denotes the correction from quark masses ($\delta_m^{tot} \approx 0.009$). In the case of the R_τ^{kl} moments of the invariant mass distribution $d\Gamma_{ud}/ds$ of the Cabbibo allowed decays, which are defined by the relation [1]:

$$R_\tau^{kl} = \frac{1}{\Gamma_e} \int_0^{m_\tau^2} ds \left(1 - \frac{s}{m_\tau^2}\right)^k \left(\frac{s}{m_\tau^2}\right)^l \frac{d\Gamma_{ud}}{ds}, \qquad (3)$$

where Γ_e is the electronic width of τ, the QCD prediction has the form:

$$R_\tau^{kl} = 3\,|V_{ud}|^2\, S_{EW}\, R_0^{kl} (1 + \delta_{pt}^{kl} + \delta_{SVZ}^{kl}). \qquad (4)$$

R_0^{kl} in (4) denotes the parton model prediction. (The δ_m contribution is negligible in the case of R_τ^{kl}.) The δ_{SVZ} contributions in R_τ and R_τ^{kl} denote nonperturbative QCD corrections calculated using the SVZ approach [7]

$$\delta_{SVZ} = \sum_{D=4,6\ldots} c_D \frac{O_D}{m_\tau^D}. \qquad (5)$$

The parameters O_D in Eq.(5) denote vacuum expectation values of the gauge invariant operators of dimension D. The c_D coefficients are in principle power series in the strong coupling constant, which depend on the considered quantity.

The contribution from the $D = 4$ term in the SVZ expansion for R_τ may be reliably expected

*Address after October 1, 1996: Centre for Particle Theory, Department of Physics, University of Durham, South Road, Durham DH1 3LE, UK.

To appear in the Proceedings of the Fourth International Workshop on Tau Lepton Physics, 16-19 September 1996, Estes Park, Colorado, U.S.A.

to be small [6], since O_4 is well constrained by the sum rules phenomenology, and the relevant coefficient function starts at $O(\alpha_s^2)$. However, the $D = 6$ contributions to R_τ is not suppressed, and there is little information on the value of O_6. It was therefore proposed [1] to treat O_D as free parameters, which are to be extracted together with α_s from a fit to the experimental data for R_τ and the higher moments of the invariant mass distribution.

The analysis reported in [1–4] involved the R_τ^{kl} moments with (k, l) equal to $(1, 0)$, $(1, 1)$, $(1, 2)$ and $(1, 3)$. However, if we are interested primarily in the possible effect of RS dependence, we may simplify the discussion by considering only the R_τ^{12} moment, for which — similarly as for the R_τ — the $D = 4$ contribution is suppressed and there is significant contribution from the $D = 6$ term. Retaining in the SVZ expansion only the $D = 6$ term, which appears to be a dominant source of the uncertainty in the nonperturbative sector, we obtain a simplest set of the QCD predictions which allows for a self-consistent extraction of α_s and O_6 from tau decays.

The perturbative QCD corrections δ_{pt}^{tot} and δ_{pt}^{kl} may be expressed as a contour integral in the complex energy plane [8], with the so called Adler function [9] under the integral. (Actually $\delta_{pt}^{tot} = \delta_{pt}^{00}$.) We have:

$$\delta_{pt}^{kl} = \frac{i}{\pi} \int_C \frac{d\sigma}{\sigma} f^{kl}(\frac{\sigma}{m_\tau^2}) \delta_{D,V}(-\sigma), \tag{6}$$

where C is a contour running clockwise from $\sigma = m_\tau^2 - i\epsilon$ to $\sigma = m_\tau^2 + i\epsilon$ away from the region of small $|\sigma|$. In the actual calculation we assume that C is a circle $|\sigma| = m_\tau^2$. The Adler function is defined by the relation:

$$(-12\pi^2)\sigma \frac{d}{d\sigma} \Pi_V^{(1)}(\sigma) = 3 S_{CKM} [1 + \delta_{D,V}(-\sigma)] \tag{7}$$

where $\Pi_V^{(1)}$ denotes the transverse part of the vector current correlator. The function $f^{12}(\sigma/m_\tau^2)$ has the form:

$$\begin{aligned} f^{12}(x) &= \frac{1}{2} - \frac{70}{13}x^3 + \frac{105}{26}x^4 \\ &\quad + \frac{126}{13}x^5 - \frac{175}{13}x^6 + \frac{60}{13}x^7. \end{aligned} \tag{8}$$

The function $f^{00}(\sigma/m_\tau^2)$ has the form:

$$f^{00}(x) = \frac{1}{2} - x + x^3 - \frac{1}{2}x^4. \tag{9}$$

The NNLO renormalization group improved perturbative expansion for $\delta_{D,V}$ may be written in the form:

$$\delta_{D,V}^{(2)}(-\sigma) = a(-\sigma)[1 + r_1 a(-\sigma) + r_2 a^2(-\sigma)], \tag{10}$$

where $a = \alpha_s/\pi = g^2/(4\pi^2)$ denotes the running coupling constant that satisfies the NNLO renormalization group equation:

$$\sigma \frac{d\,a}{d\sigma} = -\frac{b}{2} a^2 (1 + c_1 a + c_2 a^2). \tag{11}$$

In the $\overline{MS}$ scheme we have $r_1^{\overline{MS}} = 1.63982$ and [10] $r_2^{\overline{MS}} = 6.37101$. The renormalization group coefficients for $n_f = 3$ are $b = 4.5$, $c_1 = 16/9$ and $c_2^{\overline{MS}} = 3863/864 \approx 4.471$.

If the Adler function is expanded in terms of $a(m_\tau^2)$, then the σ dependence appears through the powers of $\ln(-\sigma/m_\tau^2)$. The contour integration is then straightforward and the conventional NNLO expansion of δ_{pt}^{kl} in terms of $a(m_\tau^2)$ is easily obtained. However, it was observed in [11,12] that one may also keep under the integral the renormalization group improved expression for the Adler function. In this case the contour integral has to be evaluated numerically. This results in the essential improvement of the conventional expansion, corresponding to the all-order resummation of some of the corrections arising from analytic continuation from spacelike to timelike momenta.

The QCD predictions calculated in the next-to-next-to-leading order (NNLO) approximation with massless quarks depend on two RS parameters, which in principle may be arbitrary. The two-parameter freedom in NNLO arises because in each order of perturbation expansion we are free to choose independently the finite parts of the coupling constant renormalization constant. Different choices of the finite parts of the renormalization constants result in different definitions of the coupling constant, which are related by finite renormalization. (The formulas describing how the redefinition of the coupling affects the

coefficients r_i and c_2 are collected for example in [13].) Also the dimensional QCD parameter Λ depends on the choice of the RS. In the NNLO there exists however a RS invariant combination of the expansion coefficients [15,16]:

$$\rho_2 = c_2 + r_2 - c_1 r_1 - r_1^2. \qquad (12)$$

For the Adler function we have $\rho_2 = 5.23783$.

The change in the expansion coefficients and the change in the coupling constant compensate each other, but of course in the finite order of perturbation expansion such compensation may only be approximate, which results in the numerical RS dependence of the perturbative predictions. There has been intensive discussion on the prescriptions for making an optimal choice of the RS [17]. One of the most attractive propostions is the choice based on the so called principle of minimal sensitivity (PMS) [15], which singles out the scheme parameters for which the finite order prediction is least sensitive to the change of RS, similarly to what we expect from the actual physical quantity. (It should be emphasized that in our case the algebraic PMS optimization equations [15] do not apply and a nontrivial numerical analysis of the perturbative prediction is required.)

The PMS optimization has to some extent a heuristic character and therefore it is important to investigate the stability of the predictions also with respect to non-infinitesimal changes of the scheme parameters. This may be done by calculating the variation of the predictions over a set of *a priori* acceptable schemes. A condition for selecting a class of acceptable schemes in NNLO has been proposed in [18]:

$$|c_2| + |r_2| + c_1|r_1| + r_1^2 \leq l\,|\rho_2|. \qquad (13)$$

This condition is based on the observation, that the schemes with unnaturally large expansion coefficients would give rise to extensive cancellations in the expression for the RS invariant ρ_2. The constant l controls the degree of cancellation in ρ_2 that we want to allow. In particular, for the conventional QCD expansion the PMS scheme lies approximately at the boundary of the region corresponding to $l = 2$ [18].

A detailed discussion of the RS dependence of δ_{pt}^{tot} has been presented in [19] and would not be repeated here. An important conclusion from [19] is that the contour integral resummation of higher order analytic continuation corrections is very important for ensuring the RS stability of the predictions. (This has been also discussed in [12]. The instability of the conventional expansion for δ_{pt}^{tot} has been discussed in [13,14,12].) Below we concentrate on the RS dependence of δ_{pt}^{12}.

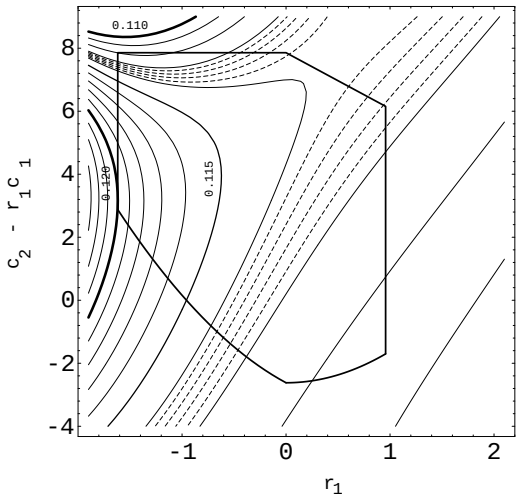

Figure 1. The contour plot of δ_{pt}^{12} as a function of the scheme parameters r_1 and c_2, for $\Lambda_{\overline{MS}}^{(3)} = 325$ MeV. For technical reasons we use $c_2 - c_1 r_1$ on the vertical axis instead of c_2. The boundary of the region of scheme parameters satisfying the Eq. 13 is also indicated.

The dependence of δ_{pt}^{12} on the scheme parameters is illustrated in figure 1 for $\Lambda_{\overline{MS}}^{(3)} = 325$ MeV. (Similarly as in the previous work [19] we parametrize the freedom of choice of the RS by the parameters r_1 and c_2, but for technical reasons we use $c_2 - c_1 r_1$ on the vertical axis of figure 1 instead of c_2.) The saddle point on figure 1 represents the PMS parameters. It is interesting, that even though the expression for δ_{pt}^{12} has es-

sentially non-polynomial character, the PMS parameters are well approximated by $r_1 = 0$ and $c_2 = 1.5\rho_2$. We shall choose these values as our optimized parameters. (The exact PMS parameters have some dependence on the value of $\Lambda_{\overline{MS}}$. Also, for very large values of $\Lambda_{\overline{MS}}$ the pattern of RS dependence is more complicated than this shown in figure 1. However, for all values of $\Lambda_{\overline{MS}}$ the RS dependence in the vicinity of $r_1 = 0$ and $c_2 = 1.5\rho_2$ is very small.) The set of scheme parameters, that involve the same — or smaller — degree of cancellation in ρ_2 than our preferred parameters, satisfies the condition (13) with $l = 2$. The boundary of this set is indicated on the figure 1. By calculating the variation of the predictions over this set of scheme parameters we may estimate in a quantitative way the sensitivity of the NNLO predictions to the change of RS. Thus obtained estimate may then be compared with a similar estimate for other quantities, for which the NNLO predictions are known. It should be noted that although the $\overline{MS}$ parameters lie outside of the "allowed" region shown in the figure 1, the numerical value of the prediction in the $\overline{MS}$ scheme is close to the lowest value attained in the "allowed" region.

It is interesting to note, that the RS dependence pattern of δ_{pt}^{12} is quite similar to the pattern found in [19] for δ_{pt}^{tot}, despite the fact that the conventional expansions for these quantities appear to be quite different. Indeed, in the conventional expansion for δ_{pt}^{tot} we have $r_1^{\overline{MS}} = 5.2023$ and $r_2^{\overline{MS}} = 26.3659$, which gives $\rho_2 = -5.4757$, while for δ_{pt}^{12} we have $r_1^{\overline{MS}} = 3.5795$ and $r_2^{\overline{MS}} = 4.3441$, which gives $\rho_2 = -10.3614$. This seems to suggest that the improved predictions obtained with contour integral expressions are more natural, reflecting the common origin of the two corrections in a better way.

In figure 2 we show the RS dependence of the next-to-leading order (NLO) prediction for δ_{pt}^{12}. By numerical optimization we find that in NLO $r_1^{PMS} \approx -0.64$. (Again, this depends to some extent on $\Lambda_{\overline{MS}}$, but this dependence has negligible effect on the numerical value of the prediction.)

In figure 3 we show the NNLO PMS predictions for δ_{pt}^{12} as a function of $m_\tau/\Lambda_{\overline{MS}}^{(3)}$, together

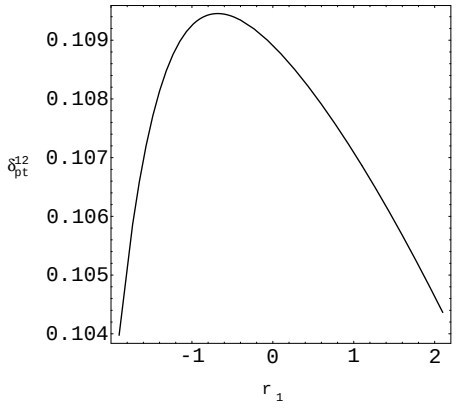

Figure 2. NLO prediction for δ_{pt}^{12} as a function of the scheme parameter r_1, for $\Lambda_{\overline{MS}}^{(3)} = 325$ MeV.

with the minimal and maximal values obtained by varying the scheme parameters within the region determined by the condition (13) with $l = 2$. We see that the NNLO predictions for δ_{pt}^{12}, obtained by numerically evaluating the countour integral expression (6), are free from potentially dangerous RS instabilities, even for large values of $\Lambda_{\overline{MS}}^{(3)}$. This situation is similar to that encountered for δ_{pt}^{tot}. For comparison we also show the PMS predictions obtained in the next-to-leading order (NLO). We see that RS dependence of the NNLO expression within the region defined by the condition (13) is smaller than the difference between NNLO and NLO PMS predictions. In a separate figure we show the NNLO and NLO predictions in the $\overline{MS}$ scheme (figure 4).

In order to see, how the optimization of the scheme parameters affects the fits to the experimental data, we first test the accuracy of the approximation in which one only retains the O_6 contribution in the SVZ expansion. To this end we make a fit of α_s and O_6 in the $\overline{MS}$ scheme and compare the results with the fit performed by ALEPH [3], in which the O_4, O_6 and O_8 contributions have been taken into account in the (1,0), (1,1), (1,2) and (1,3) moments. To make

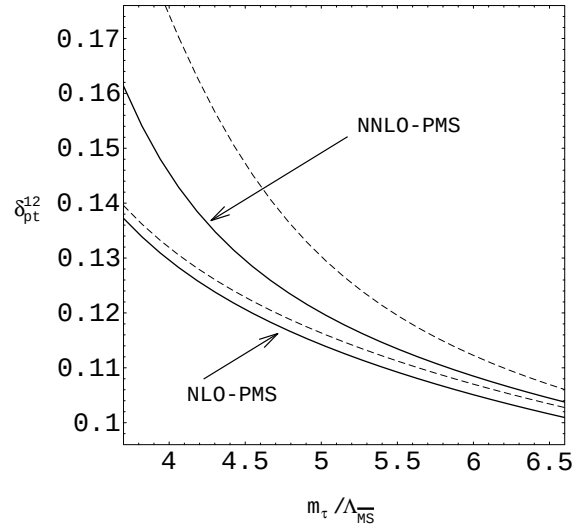

Figure 3. The optimized predictions for δ^{12}_{pt}, as a function of $m_\tau/\Lambda^{(3)}_{\overline{MS}}$, obtained in NNLO (upper solid curve) and NLO (lower solid curve). The dashed lines indicate variation of the predictions when the scheme parameters are changed within the region satisfying the Eq. 13.

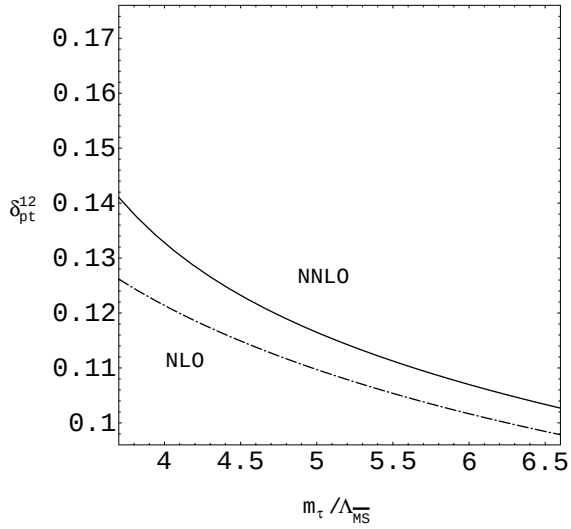

Figure 4. δ^{12}_{pt} as a function of $m_\tau/\Lambda^{(3)}_{\overline{MS}}$, obtained in the $\overline{MS}$ scheme in NNLO (upper curve) and NLO (lower curve).

the fits we use the following expressions:

$$R_\tau = 3 \times 1.0194\,(0.991 + \delta^{tot}_\tau - 3.75\,O_6), \qquad (14)$$

and

$$D^{12}_\tau = R^{12}_\tau / R^{00}_\tau = \frac{13}{210}\frac{(1 + \delta^{12}_\tau + 20.16\,O_6)}{(1 + \delta^{tot}_\tau - 3.75\,O_6)}. \qquad (15)$$

If we take, following ALEPH [3], $R_\tau = 3.645 \pm 0.024$ and $D^{12}_\tau = 0.0570 \pm 0.0013$, we obtain from the fit in the $\overline{MS}$ scheme $\alpha_s(M_Z^2) = 0.1209 \pm 0.0013$ and $O_6 = -0.0010 \pm 0.0012$. This appears to be remarkably close to the values 0.121 and -0.0016 obtained in the full fit by ALEPH. This gives us confidence that the "O_6 approximation" captures the essential features of QCD corrections in τ decays.

Let us now study how the RS dependence may affect the fit to the experimental data. Let us take $R_\tau = 3.635 \pm 0.016$, which is a weighted average of three possible determinations [20], involving $B_e = 0.1783 \pm 0.0008$, $B_\mu = 0.1735 \pm 0.0010$ and $\tau_\tau = (291.0 \pm 1.5) \times 10^{-15}$sec. (These are the so called "our fit" values. Using a set of "our average" values given in [20] we would obtain $R_\tau = 3.643$.) Let us also take [4] $D^{12}_\tau = 0.0559 \pm 0.0007$, which is the most precise published value up to date. Using the NNLO PMS expression we obtain then $\alpha_s(M_Z^2) = 0.1188 \pm 0.0008$ ($\alpha_s(m_\tau^2) = 0.330 \pm 0.008$) and $O_6 = -0.0021 \pm 0.0006$. Performing the same fit, but using now the NNLO $\overline{MS}$ expression, we obtain $\alpha_s(M_Z^2) = 0.1198$ and $O_6 = -0.0020$. We see that the value of the condensate practically does not change, but the value of the strong coupling constant is reduced by amount approximately equivalent to the experimental error.

It is also of some interest to repeat the fit using the NLO PMS expression. We then obtain $\alpha_s(M_Z^2) = 0.1210$ and the same value for O_6 as in NNLO. Taking the difference of the NNLO and

NLO PMS fits is perhaps the best way of estimating the accuracy of the perturbative contribution in this problem, since we found the QCD corrections to be quite stable with respect to change of the scheme. We see that thus obtained uncertainty of the fitted value of α_s is of the order 0.0022, i. e. it is quite large, compared for example to the experimental uncertainty. (This estimate of uncertainty involves only the perturbative uncertainty — to have estimate of theoretical uncertainty for the total QCD prediction one should also consider the accuracy of the SVZ expansion itself.) It should be noted that the NNLO-NLO difference is strongly RS dependent so it is essential to optimize the choice of the scheme before comparing the predictions in successive orders.

Concluding, the renormalization scheme dependence of the perturbative QCD corrections to R_τ and to the R_τ^{12} moment of the invariant mass distribution in hadronic tau decays has been studied in detail. The optimized predictions have been obtained using the principle of minimal sensitivity as a guide to select the preferred renormalization scheme. The stability of the predictions obtained via the contour integral expression (6) has been verified, using a specific condition to eliminate the schemes that have unnaturally large expansion coefficients. However, the difference between predictions in the conventionally used $\overline{MS}$ scheme and the optimized predictions obtained in the PMS scheme was found to be phenomenologically significant. Also, the difference between the NNLO and NLO predictions in the PMS scheme was found to be significant, indicating perhaps that the uncertainty in the perturbative expression is larger than previously expected.
